This manuscript was compiled on May 7, 2020

1 Biological evolution occurs in the context of complex networks of
2 interacting species in which natural selection defines the structure
3 of ecological networks. Fundamental to this evolutionary process
4 is the discovery of a genetic basis to ecological network structure.
5 Although previous work has demonstrated that tree genotype con-
6 tributes to interaction network structure at the scale of forest stands,
7 the contribution of tree genetics to localized interaction networks
8 at the scale of individual trees has not yet been explored. To test
9 the degree to which tree genetics can contribute to network struc-
10 ture we conducted quantitative modeling of interaction networks. We
11 constructed networks of epiphytic lichen associated with individual
12 trees that were a part of a long-term experimental common garden
13 of genotypes of (*Populus angustifolia*), a foundation species. We
14 found three main results. First, tree genotype significantly predicted
15 lichen network similarity, i.e. trees of the same genotype had more
16 similar lichen networks. Second, bark roughness and condensed
17 tannin concentration were both predicted by tree genotype and cor-
18 related with lichen network similarity. Third, the network metrics, the
19 number of links and centrality, were both correlated with several tree
20 traits, including bark roughness and condensed tannin concentra-
21 tion. We conclude that tree genotype influences lichen interaction
22 network structure with two potential pathways through bark rough-
23 ness and condensed tannin concentration. These results provide
24 evidence that variation in ecological networks can result from genet-
25 ically based variation in foundation species.

networks | heritability | community | genetics | lichen | cottonwood |
Populus | common garden

- 1 Evolution occurs in complex ecosystems
- 2 Community genetics studies have demonstrated
3 the importance of genetics and evolutionary dynamics in structuring communities and ecosystems
- 4 Community composition, ecosystem processes have been shown to vary in response to the genetic variation of foundation species
- 5 Previous studies have examined aspects of networks but to date, no studies have examined the genetic basis of networks of interacting species
- 6 Here we examine the genetic basis of network structure on a community of sessile lignicolous

(i.e. bark) lichen on cottonwood trees. This system is ideal for examining for this kind of study because it:

- 1 Lichen do not move among trees, although
2 asexual propagules could move to other
3 trees in the garden
- 4 Is not unapproachably complex
- 5 Is comprised of distinct individuals that
6 are small enough for an entire community
7 to occur on a single tree but not too small
8 to be quantified easily

Significance Statement

Evolution occurs in the context of ecosystems comprised of complex ecological networks. Research at the interface of ecology and evolution has primarily focused on pairwise interactions among species and have rarely included a genetic component to analyses. Here, we use a long-term common garden experiment to reveal the effect that genotypic variation can have on networks of lichens that occur on the bark of a foundation tree species. We found that lichen interaction network structure is genetically based and is correlated with heritable bark traits, including roughness and condensed tannins. These findings demonstrate the importance of genetic variation and evolutionary dynamics in shaping ecological networks as evolved traits.

M.L. and L.L. conceived the study, M.L. and L.L. conducted the field work, R.N. assisted in lichen identifications, M.L. wrote the first draft of the manuscript, S.B. and T.W. contributed substantively to the conceptual development, T.W. established the common garden. All authors contributed to revisions of the manuscript.

The authors have no conflicts of interest.

¹Dr. Matthew K. Lau. E-mail: matthewklau@fas.harvard.edu

- 25 • We hypothesize that trees will vary in some
 26 phenotypic traits, such that trees of the same
 27 genotype will tend to have similar traits produc-
 28 ing similarities in lichen network structure. To
 29 test this hypothesis, we use a common garden
 30 of cottonwood trees with lichen communities.

31 **E**volution occurs in the context of complex eco-
 32 logical networks. Initially, evolution in a com-
 33 munity context was focused on examples of highly
 34 co-evolved pairs of species (e.g. Darwin's famous
 35 prediction of the Sphinx Moth and Christmas
 36 Orchid) citeWade2007. However, studies of dif-
 37 fuse co-evolution (*sensu* citeJanzen1980) citeStinch-
 38 combe2002, Strauss2007, Dicke2010, geographic mo-
 39 saics of co-evolution citeThompson2005 and com-
 40 munity genetics citeWhitham2006 have provided an
 41 in-road for ecological network approaches citeFor-
 42 tuna2009, Keith2017, Lau2016 to illuminate a more
 43 complex perspective of the interface between eco-
 44 logical and evolutionary dynamics. There is now
 45 evidence to support that selection tends to occur
 46 among groups of species citeWade2007, Pieterse2007,
 47 Dicke2010 favoring the development of small webs
 48 citeNuismer2006, Guimaraes2007, Gomez2009 and
 49 that genetic variation and phylogenetic relatedness
 50 contributes to variation in community assembly (1)
 51 and species interactions citeWhitham2006a, Bai-
 52 ley2009, Moya-Larano2011, which shapes the eco-
 53 logical interaction networks (2).

54 Community genetics studies (3) have shown that
 55 genetic variation in foundation species (4) plays a
 56 significant role in defining distinct communities of in-
 57 teracting organisms: such as, endophytes, pathogens,
 58 lichens, arthropods, and soil microbes. Multiple stud-
 59 ies have now demonstrated that genetic variation
 60 influences numerous functional traits (e.g., phyto-
 61 chemical, phenological, morphological) produces a
 62 multivariate phenotype (5) that contributes to varia-
 63 tion in associated communities (6). The importance
 64 of genetic variation in structuring ecological systems
 65 was recently reviewed by Des Roches et al. (2018).

66 Additional work has provided support for the hy-
 67 pothesis that not only does composition vary among
 68 genetically distinct genotypes of foundation species,
 69 it also impacts the structure of the network of species
 70 interactions in these communities. Two studies have
 71 demonstrated conceptually (7) and empirically (8).
 72 However, studies in the network ecology literature
 73 generally do not include a genetic component (see

74 review by Borrett et al. 2014) and community genet-
 75 ics papers do not have data on network structure of
 76 associated communities. Currently, we are aware of
 77 only one paper that empirically examines the genetic
 78 basis of network structure of a community citeBar-
 79 bour2019.

80 Here, we investigate how genetic variation in a
 81 foundation tree species determines the structure of a
 82 network of interactions among a community of tree
 83 associated lichen species. Using a long-term (20+
 84 years), common garden experiment with replicated
 85 individuals of known genetic identity and a naturally
 86 established stand of *Populus angustifolia*. We focused
 87 on a model community of 9 epiphytic lichen species,
 88 as previous research has demonstrated significant
 89 compositional responses of epiphytes to genotypic
 90 variation (9, 10). In addition, the life-history char-
 91 acteristics of lichens, having highly localized, direct
 92 contact interactions and slow population turnover
 93 rates, allowed us to assess interactions among lichen
 94 species on individual trees. We hypothesize that in
 95 natural systems evolution occurs in a community
 96 context involving interactions of complex networks
 97 of interacting species (7, 8, 11, 12). If correct, we
 98 expect to find that network structure is genetically
 99 based in which different plant genotypes support
 100 different interaction networks and that these interac-
 101 tions networks can function as indicators of ecologi-
 102 cal dynamics important for conserving biodiveristy.
 103 Applying a probability-theory based network mod-
 104 eling approach, we constructed a set of interaction
 105 network models for the lichens associated with indi-
 106 vidual trees. Using these models, we then examined
 107 the genetic basis of the structure of these ecological
 108 networks.

Materials and Methods

109 The study was conducted along the Weber River, UT
 110 (USA), which is a cottonwood (*Populus* spp.) dominated
 111 riparian ecosystem. Although two native species, *Populus*
 112 *angustifolia* (James) and *Populus fremontii* (S. Watson),
 113 occur here and are known to hybridize, only pure or
 114 advanced generation backcrosses of *P. angustifolia* were
 115 sampled. Bark lichens have been extensively studied
 116 in this system and provide an ideal system in which to
 117 observe and model lichen interaction networks, as their
 118 sessile nature permits accurate identification of individuals
 119 (13).

120 A long-term, common garden experiment was used
 121

123 to isolate the effect of tree genotype from the effect of
124 the localized microenvironment associated with each individual and spatial autocorrelation. Established in 1992,
125 asexually propagated clones of genotyped *P. angustifolia* individuals were obtained from wild collections and
126 planted in fully randomized design at the Ogden Nature
127 Center, Ogden, UT. From the population of established
128 individuals in the common garden, we chose a total of
129 thirteen genotypes, replicated between 3 and 8 times each,
130 for sampling.
131

132 **Bark Lichen Observations.** On each tree, presence or absence of each lichen species was assessed in 50 total 1 cm² cells arrayed in a checkerboard pattern. Given the small size and sessile nature of lichens, we were able to rapidly assess lichen interactions by quantifying thalli in close contact. Sampling was restricted to the northern aspect of the trunk to maximize the abundance of lichen and control for the effect of trunk aspect. Two adjacent 10 cm² quadrats centered at 50 cm and 85 cm from ground level were sampled (Fig 1 A and B). The observed lichen community included (abbreviations are given for species present in study): Xg = *Xanthomendoza galericulata*, Xm = *X. montana*, Ch = *Caloplaca holocarpa*, Cs = *Candulariella subdeflexa*, Rg = *Rinodina glauca*, Lh = *Lecanora hagenii*, Pm = *Phyciella melanchra*, Pa = *Physcia adscendens*, Pu = *Physcia undulata*. Several other species were not observed in the present study but are known to occur in this region: *Phaeophyscia orbicularis*, *Phaeophyscia ciliata*, *Melanelia sublivacea*, *Meanelia elegantula*.

133 The cell size and checkerboard sampling pattern was chosen to isolate the individuals in each cell. In a previous survey of lichen thallus size in this common garden, we had observed a median thallus size of 0.12 ± 0.001 cm² (1 S.E.) (see Supporting Information). Based on the median thallus size, we expected thalli observed in each cell to generally be spatially independent of thalli present in other cells but exposed to similar micro-environmental conditions created by the bark and the location of the sampling area on an individual tree. Therefore, we were confident in treating the cell-wise observations in quadrats as independent with respect to lichen-lichen interactions.

134 We also measured several bark traits for each tree:
135 including, bark roughness and chemistry. **INSERT
136 FROM LAMIT.**

137 **Lichen Network Modeling and Analysis.** For each tree,
138 repeated observations of lichen were made in order to construct replicated interaction networks for each genotype.
139 We quantified the presence of lichen in the 1 cm² cells on individual trees of *P. angustifolia*. Unipartite networks were generated using the conditional probabilities of each species pair, i.e. the probability of observing one species given an observation of another species $P(S_i|S_j)$, based on the method developed by (14). To calculate conditional probabilities, we quantified the individual probabilities

140 of species occurrences $P(S_i)$ and the joint probability
141 of co-occurrences $P(S_i, S_j)$ using the frequencies of each species and their co-occurrences. We were then able to
142 calculate the conditional probabilities of each species pair
143 as $P(S_i|S_j) = \frac{P(S_i, S_j)}{P(S_j)}$, based on the axioms of probability.
144 This yielded a matrix that could possibly be asymmetric, i.e.
145 $P(S_i|S_j)$ does not have to be equal to $P(S_j|S_i)$. Another
146 important property of this matrix is that the diagonal
147 (S_{ii}) was equal to one for all species present and zero for
148 species that were not observed in any cell.
149

150 We then applied an analytical procedure to remove
151 non-significant links between species. This procedure
152 determines if the joint probability of a species pair
153 (i.e. $P(S_i, S_j)$) is different from zero (Fig. 2). Here, a
154 confidence interval $CI_{95\%}$ is calculated as $CI_{95\%} = E[S_i S_j] * Z_{95\%} * \sqrt{V(S_i S_j)}$, where the expected frequency of co-occurrences $E(S_i S_j)$ is the total number of cells surveyed (N) times the independent probabilities of each species $P(S_i) * P(S_j)$, $Z_{95\%}$ is the Z-score for 95% from a Z-distribution and the expected variance of $E(S_i S_j)$ is the total number of cells times the expected probability of $S_i S_j$ and its compliment (i.e. $V(S_i S_j) = N * E[P(S_i, S_j)] * (1 - E[P(S_i, S_j)])$). If the observed number of co-occurrence falls outside of the confidence interval, the joint probability $P(S_i, S_j)$ is determined to be equal to the product of the individual probabilities (i.e. $P(S_i)P(S_j)$), and the conditional probability reduces to the individual probability of that species $P(S_i)$. Therefore, unless the co-occurrence of a species pair falls outside the confidence interval, the probability that the observation of one species given the other is no different than simply observing that species alone. This enables us to remove links from a given network by re-scaling the resulting conditional probabilities by subtracting the individual probabilities from the conditional probabilities (i.e. how different the conditional probability is from the independent probability), which makes any species with a non-significant conditional probability zero. The resulting matrix ($\mathbf{D} = D_{ij}$) can be interpreted as how one species impacts another with zero being no effect and values less than or greater than zero interpreted as negative and positive effects, respectively. Here, we will refer to this matrix (\mathbf{D}) as an interaction matrix with the properties that it can be asymmetric (i.e. P_{ij} does not necessarily equal P_{ji}), and the diagonal (P_{ii}) is zero (i.e. a species does not influence its own probability of being observed).

155 **Statistical Analyses, Software and Data.** We used a combination of parametric and non-parametric, permutation
156 based frequentist statistical analyses to test for the effects
157 of genetic variation on lichen communities and their interaction
158 networks. To assess the effect of genotype on univariate
159 responses, we used additive, random effects models
160 with Restricted Maximum Likelihood (REML). We used
161 a combination of Least Squares Regression, Analysis of

Fig. 1. The communities of bark lichens were observed in a common garden of replicated genotypes of narrowleaf cottonwood trees (*P. angustifolia*) at the Ogden Nature Center (Ogden, UT). Lichens were sampled within a fixed area (10 cm^2) on individual trees at two heights, 40cm and 80cm from the ground (A and B, respectively). (C) a photo of a typical community of bark lichen species interacting on the trunk of a cottonwood tree, including one of the more abundant species, *Xanthomendoza galericulata*, in the center. (D-K) shows the other lichen species observed, respectively: *X. montana*, *Candelariella subdeflexa*, *Rinodina* sp., *Caloplaca holocarpa*, *Physcia adscendens*, *Phyciella melanchra*, *Physcia undulata* and *Lecanora hagenii*. Photo Credits: L.J. Lamit (A-C) and R.R. Naesbourn (D-K).

232 Variance (ANOVA) and correlation tests to quantify and
 233 test for the relationship among other variables. Bark
 234 roughness, lichen cover and species richness were square-
 235 root transformed to meet the assumptions of homogeneity
 236 of variance and normality for these tests.

237 For multivariate response variables, such as lichen com-
 238 munity composition and network structure, we used dis-
 239 tance based multivariate statistical approaches, including
 240 Permutational Analysis of Variance (PERMANOVA) and
 241 Mantel tests. For some analyses, community composition
 242 was relativized by species maxima to reduce the effect
 243 of the highly abundant *X. galericulata*. For community
 244 composition we used Bray-Curtis dissimilarity, which has
 245 optimal performance with count data citepMinchen1998.
 246 To quantify the similarity of lichen networks among indi-
 247 vidual trees, we calculated the pairwise Euclidean distance
 248 of the **D** interaction matrices among all pairs of trees.

249 For visualization of multivariate patterns, we used Non-
 250 metric Multi-Dimensional Scaling (NMDS) citeecodist
 251 to produce dimensionally reduced ordinations of these
 252 multi-variate responses and fitted vectors for continuous
 253 predictor variables to the ordinated values citevegan. Us-
 254 ing random initial configurations with a maximum of 500

iterations and a change in stress threshold of less than
 10^{-12} . Final configurations has the lowest stress with at
 most a stress level of 0.10.

255 For each network, we also calculated metrics that mea-
 256 sure different structural aspects. Although there are many
 257 other metrics, for the sake of simplicity we focus on a sub-
 258 set that represent several interesting features of network
 259 structure (see (15)). We calculated the number of interac-
 260 tions or “links” in each network, which provides a measure
 261 of the size of the network citepLau2015, Borrett2014. We
 262 also calculated the centralization of each network, which
 263 measures the evenness of the distribution of interactions
 264 among the species in the network citeButts2005. In a net-
 265 work with a low level of centralization species have similar
 266 amount of interaction in the network, while a network
 267 with a high level of centralization tends to have one or
 268 small number of species that interact with other species.
 269 We used a related function to calculate the centrality of
 270 each species (i.e. node level centrality) in each network
 271 as well. The modularity of each network was also quanti-
 272 fied using a weighted algorithm citeBeckett2016, which
 273 measures the degree to which a given network is divided
 274 into groups of species more connected to each other than
 275

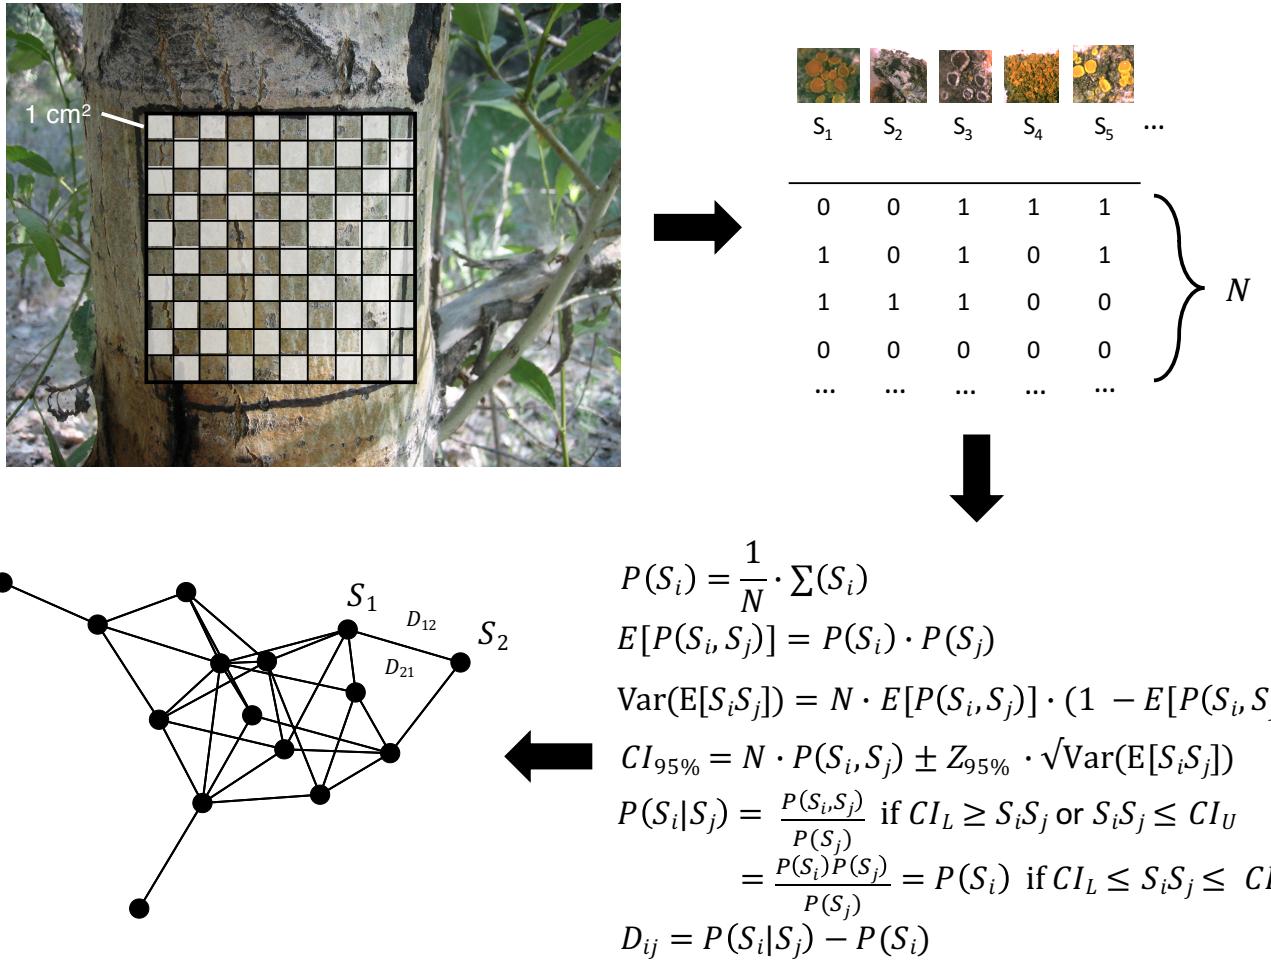

Fig. 2. Lichen interaction networks were constructed by conducting field observations in 1 cm^2 cells within a 10 cm^2 grid on each tree using a checkerboard pattern (grey cells). Thus, a set of N total cell observations were recorded for each tree with the presence or absence of each species recorded for each cell. Applying the probability-based network modeling method adapted from (14), we calculated the conditional probabilities, $P(S_i | S_j)$, for all species pairs and removed (i.e. set equal to zero) species pairs whose joint probabilities, $P(S_i, S_j)$, were not significant using a confidence interval based comparison of their observed co-occurrence frequency, $S_i S_j$, to that expected due to chance alone, $E[P(S_i, S_j)] = P(S_i) P(S_j)$, and $P(S_i | S_j)$ reduces to $P(S_i)$, the observed individual probability of species S_i .

other species. As with the other response variables, the number of links was log-transformed and both modularity and centralization scores were fourth-root transformed to meet variance and normality assumptions.

All code and data for the project are openly available online. Code and data are available at github.com/ecgen/comgen. The project is also archived via Zenodo at zenodo.com/doi/XXXXXX. All analyses were conducted using the programming language R version 3.6.1 (R Development Core Team 2019).

Results

1. Network structure responded to genotype
 - number of links responded
 - centrality responded
 - average mutual information responded

- Figure: chplot network metrics

2. Genotype indirectly influenced networks through bark roughness

- genotype predicted bark roughness (reml)
- bark roughness predicted network metrics (L, Cen, AMI)
- Bark roughness was negatively correlated with L, Cen and AMI
- genotype did not predict any residual variation in lichen networks from bark roughness' effect
- Genotype didn't predict any other measured traits

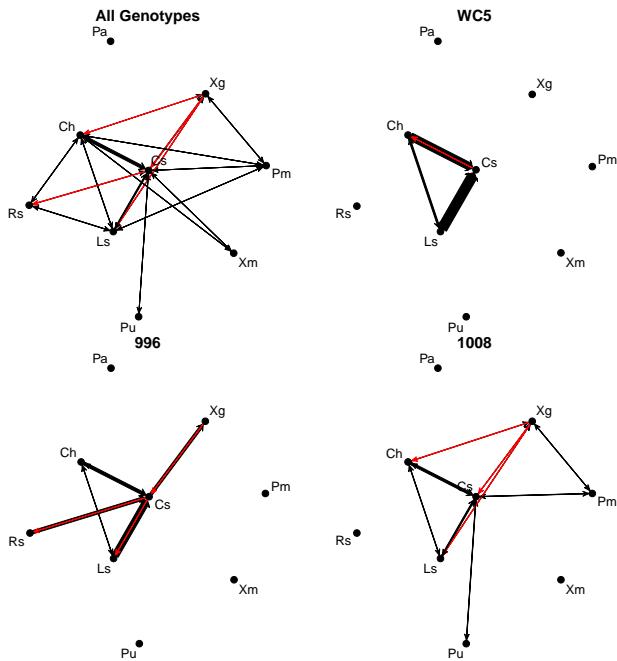

Fig. 3. Lichen networks varied in structure among tree genotypes. Network diagrams of the mean lichen interaction matrices averaged for all trees and for several individual genotypes showing a range of interaction network structure. Directionality (arrowheads) and sign (red = negative, black = positive) of interactions are shown as edges between species (abbreviated by the first letter of the genus and specific epithet), which are scaled by their magnitude. The sign of the interaction is indicative of greater (positive) or lesser (negative) paired occurrences than expected relative to the overall frequency of occurrence of each species. Ecologically, the links in the network are likely the product of multiple types of interactions (e.g. mutualism, parasitism, competition, facilitation) that could vary over both space and time.

predictor of network similarity ($H^2 = 0.16$, *p-value* ≤ 0.001). Bark roughness ($H^2 = 0.38$, *p-value* ≤ 0.001) and condensed tannin concentration ($H^2 = 0.28$, *p-value* = 0.014) also showed a signature of tree genotype (Fig. 2); however, this was not the case for other tree traits, bark pH and carbon to nitrogen ratio. Also, none of the lichen network metrics were significantly predicted by tree genotype, either at the scale of the entire network (Table 1) or for individual species (see Supporting Information). Although both showed a response to tree genotype, bark roughness and condensed tannins were not correlated (Pearson's $r = 0.084$, *p-value* = 0.556).

Table 1. Genotypic effects on the associated lichen community.

Tree traits and lichen community metrics were correlated with lichen networks. The genetically based traits, bark roughness and condensed tannins were both significant predictors of network similarity (Table 2). Bark C:N ratio was also a significant predictor of network similarity, but, as shown previously (see Table 1), there is not sufficient evidence support a genetic basis for it. Bark pH was not a significant predictor of lichen network similarity (Table 2). The abundance, richness, evenness and diversity of the bark lichen community, although also not predicted by tree genotype, were all significantly correlated with lichen network structure (Table 2). Lichen community composition was not correlated with lichen network similarity, either when species abundances were relativized (Mantel R = -0.09, *p-value* = 0.139) or not (Mantel R = -0.03, *p-value* = 0.573).

- No other bark traits predicted network metrics

3. Centrality was a collective response

- centrality varied among species
- individual species centrality did not respond to genotype
- mantel?
- Figure: barplot + post-hoc

4. The lichen networks also responded to non-genetically based variation in the community

- Bark roughness not correlated with lichen PC, SR, SE, SD
- PC negatively correlated with Cen
- SR positively correlated with L
- SE positively correlated with L
- SD positively correlated with L, Cen

Network similarity and several tree traits were genetically based. Tree genotype was a significant

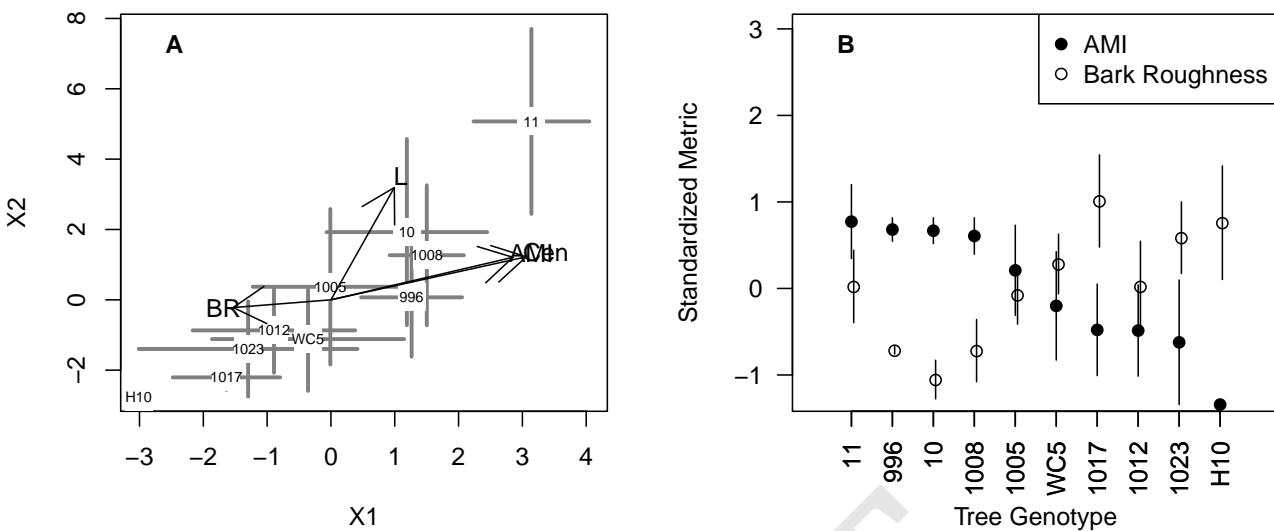

Fig. 4. Tree genotype affected lichen networks and several bark traits. A. The plot shows genotype centroids of NMDS ordinated ($R^2 = 0.999$, stress = 0.008) lichen networks (± 1 S.E.). Centroids that are closer are more similar in the structure of their lichen networks. B. Plot showing the standardized ($\frac{x - \bar{x}}{\sigma}$) means (± 1 S.E.) for the two genetically based tree traits: tree bark roughness and condensed tannin concentration.

Discussion

- We found:
 - Lichen networks genetically based
 - Bark roughness was the primary genetically based trait driving network structure
 - Lichn networks also varied with cover, richness and diversity of the lichen community, which were not correlated with roughness and primarily driven by one dominant species
- What mechanisms could be at play?
 - Habitat filtering of communities (richness, composition) vs environmental influence on interactions. Likely a combination of both of these factors.
 - Lichen network structure correlated with species richness, evenness and diversity

- Lichen community composition not correlated with network structure
- None of these were genetically based
- An important consequence for diversity is that genotypes could be supporting unique communities, even if the composition of the communities is the same among individuals and genotypes.
- Genetic diversity could be influencing the stability of communities through the effects on interactions. Some network structures are likely to be more stable, either in response to disturbance or via self-organized dynamics. Although, none of the metrics examined, such as the number of links, modularity or centrality, showed a genetic signature.
- Important factors to consider in studies of other ecological networks:
 - Relative body size
 - Mobility
 - Reproductive isolation
- Future work should consider the potential influence on evolutionary dynamics of communities

- 393 – Network structure influences network sta-
394 bility
395 – Are the communities nested subsets?

396 **TGW: I think window is too vague and this**
397 **topic sentence needs to be much stronger for**
398 **a journal like PNAS. Might be stronger by**
399 **saying "Our findings argue there is a genetic**
400 **component to network structure, which im-**
401 **pplies that network structure could be subject**
402 **to selection and networks can evolve."**

403 **TGW: Could we also make the comparsion**
404 **that genetically more similar trees also have**
405 **more similar communities? We've done this**
406 **in the past and it has worked, e.g., Randy's**
407 **genetic similarity rule.**

- 408 • Genetic assembly rule = similar genetics will
409 have more similar communities
- 410 • What we don't know is whether or not these
411 interactions will also lead to similar interactions
412 among other species.
- 413 • Thus, it would be possible for genetics to not
414 only influence other species directly, but also
415 indirectly by influencing the interactions among
416 other species.

417 We observed significant lichen interaction struc-
418 ture that varied among genotypes of a foundation
419 tree species, narrowleaf cottonwood (*P. angustifo-*
420 *lia*). We found that a genetically based trait, bark
421 roughness, partially explained the variation in lichen
422 interaction networks. Some of this variation in lichen
423 networks was related to both the overall abundance
424 and species richness of lichen; though, statistically
425 controlling for the effect of genotype on these vari-
426 ables indicates that a significant portion of the vari-
427 ance in lichen species richness is due to a factor
428 other than tree genotype. By using network metrics,
429 we were also able to probe for specific characteris-
430 tics of how these networks were responding to tree
431 genotype. We found that both number of links and
432 the centralization of the networks were highly corre-
433 lated with network similarity and that tree genotype
434 significantly predicted network centrality but only
435 marginally predicted the number of network links.
436 This latter result could be due to the relationship
437 between species richness and the number of links
438 in the network, which were significantly correlated

439 with each other. We also found that bark roughness
440 did not significantly predict either the number of
441 links or the centrality of lichen networks, suggesting
442 that bark roughness has some other effect on the
443 structure of the lichen networks. Taken together,
444 these findings support the hypothesis that genotypic
445 variation in a foundation species contributes to the
446 structure of a network of interacting species.

447 **LJL: I wonder if you need to have so much**
448 **on richness here. Overall, I think you want to**
449 **focus on the network reponses and patterns**
450 **among genotype first, and then go into mech-**
451 **anism later. I think we don't quite have a**
452 **good mechanism yet so I don't think it needs**
453 **to come up in the first paragrph of the dis-**
454 **cussion.**

455 These findings point to the importance of under-
456 standing the community level effects of genetic varia-
457 tion in plant functional traits and highlights the
458 potential for indirect effects of genetic variation to
459 propagate through networks of interacting species
460 and trophic levels.

461 This work corroborates previous findings of the
462 importance of plant genetics in shaping community
463 structure and ecosystem processes. citepBangert2008

464 Altering the structure of interaction networks
465 presents a means for genetic effects to be magni-
466 fied within the system of interacting species. For
467 example, (8) showed that the genetics based interac-
468 tions of aphid resistant and aphid susceptible trees
469 resulted in different interaction networks of their
470 associated arthropod communities composed of 139
471 species. At the scale of ecosystems, trophic net-
472 works or food webs direct and control the rates of
473 energy and nutrient flux (16). Furthermore, in a
474 predator-prey-plant study, Smith (17), showed that
475 the interactions among species across trophic levels
476 depended on plant genotype.

477 Also, work by (18–20) observed consistent pat-
478 terns of centralized interactions of species modules
479 focused around hubs of plant-fungal interactions. In
480 other words, a small number of plant and fungal
481 symbionts tended to have disproportionate numbers
482 of interactions with other species and likely are the
483 drivers in determining community assembly, struc-
484 ture and dynamics.

485 More on the importance of ecological networks
(21, 22).

486 From Thompson2014

- 488 • Pairwise interactions are usually influenced by
489 other species
- 490 • Selection favors the development of small webs
- 491 • Evolution of new lifestyles leads to changes in
492 selection on large and small webs

493 Specific hypothesis from Thompson2014

494 **LJL:** If I recall, the Elamo paper just looks
495 at genetic correlations between pairwise individual
496 abundances. I would suggest maybe it
497 doesn't deserve to be in this 1st paragraph.
498 Perhaps it actually should be in the 2nd or
499 3rd paragraph, just as a reference that points
500 to the potential for genotype to influence networks.
501 Definately our 2015 JOE paper goes
502 much further, too, since it has whole communities
503 being correlationed. But, again, I
504 woudl put both of these as citation in the community
505 genetics paragraphs (2 of 3) instead
506 of the first paragrpah, which focuses on the
507 general network lit.

508 **LJL:** It could be useful to point out that
509 our findings are not related to trophic interactions,
510 which is pretty cool. Also,we talk
511 about interaction networks but it is not clear
512 to me if the interactions tend to be positive
513 or negative. Can we get at that with the approach used?

515 **TGW:** Is there any adaptive component to
516 the tree in having certain lichen communities?
517 e.g., can they feed back to affect tree
518 performance in some way or is this a passive
519 outcome of a trait that affects bark for
520 other adaptive reasons and lichens are passive
521 players that tag along for the ride? I
522 could envision that lichens covering the bark
523 of a tree act as a barrier between insects and
524 pathogens, much like ectomycorrhizae cover
525 fine roots as a first line of defense by invading
526 microorganisms. Uptake of N that gets
527 passed to the tree??

528 **LJL:** I agree that there is a general overarching
529 theme that evolution occurs in a community
530 network context, but I'm not sure
531 that we should state that as our main hypothesis.
532 It seems more that this is a fundamental
533 foundation for our work. The hypothesis
534 is more what we are testing directly, but
535 we don't test this directly. I guess I don't

want to give the impresison that our communities
536 are necessarily the result of each
537 species evolving into its place in the community
538 on these tree genotypes (although I do
539 understand this as Shuster et al 2006's fundamental
540 explanation for why we see different
541 communities on different genotypes; I don't
542 necessarily agree that this is the only reason
543 we woudl see different communities on
544 dif genotypes). Most of these are pretty generalist
545 lichens, which could be found on other
546 deciduous trees in the surrounding city or natural
547 areas. I would look at it more like an
548 assembling of lichen species into unique configurations
549 on genetically different substrates.
550 There may be some selection for different
551 genotype of lichen during the community assembly
552 process but we can't really tell that
553 just by differences in species abundances or
554 coocurneces. I guess to me the evolutionary
555 context that is more direclty related to this
556 work is that the tree genotype is a central
557 controller (indeed a sort of hub species in the
558 network) of network structure. By anchoring
559 the lichen network to tree genotype (and
560 variation among networks to variation among
561 tree genotypes) , our study highlights the possi-
562 bility that natural selection acting on the
563 trees may have an extended consequence for
564 the network structure of organisms living on
565 the trees...the extra thing we add to the field
566 is that we show interaction networks are sen-
567 sitive to genotype. I doubt the lichens have
568 a direct effect on tree fitness, but favorabil-
569 ity of some tree genotypes over others during
570 natural selection will then go on to favor and
571 disfavor certain lichen communities of differ-
572 ent network structures. By being sensitive
573 to tree genotype, the lichen community net-
574 works are passive riders on the waves of evolu-
575 tionary dynamics that occur within the tree
576 species they inhabit.

578 **MKL:** In response to Lamit's comment
579 above, I agree that it is not required that
580 there is co-evolution. Another, perhaps sim-
581 pler, explanation is that there is variation in
582 environmental filtering of lichen individuals
583 created in part by genetic variation in tree
584 individuals.

585 TGW: might be good to cite papers on
586 competition in lichens or other organizing fac-
587 tors to back up the least expected statement.
588 as epiphytes we might not expect them to
589 care.

590 TGW: I think we need to emphasize the
591 long-term nature of our common garden
592 study as very few common garden studies of
593 lichens likely exist. Any refs on this? If true
594 might want to mention this up front in intro.

595 MKL: Environmental filtering is evidenced
596 by species richness, but also possibly species
597 interaction varying based on environment as
598 networks varied in terms of sign and magni-
599 tude as well.

600 MKL: The effect of bark roughness on
601 network similarity was primarily genetically
602 based, and there are likely other factors at
603 play.

604 Discussion of network implications for sta- 605 bility with genetics.

606 Bark roughness had previously been shown to be
607 an important tree trait influencing bark lichens (13)
608 that is under strong genetic control (23).

609 Although our study was conducted with a commu-
610 nity of lichens, these results should be generalized
611 to other groups of diverse organisms around the
612 world that also exhibit significant genetic signals at
613 the community level (24, 25). In the face of the
614 high degree of complexity and potential context de-
615 pendence of ecological processes, the current study
616 points to the utility of considering the spatial and
617 temporal scales of interactions, as discussed to some
618 in previous studies (26–28). In the present study,
619 we found that community assembly processes, such
620 as environmental filtering and species interactions,
621 are genetically based. This is likely due, in part,
622 to the large difference in the differences in size and
623 longevity of the lichen and cottonwood individuals
624 with the trees determining the environment in which
625 the lichen occur. We suggest that future work would
626 be aided by determining these modules within the
627 biotic community that include species with similar
628 differences in body-size and time-scales. As heritable
629 variation is the raw material for natural selection
630 to act upon, a genetic basis for interaction network
631 structure indicates evolutionary dynamics should be
632 considered at the community level and that con-
633 serving genetic variation is important to consider in

efforts to restore or preserve complex species interac-
634 tions and their associated ecosystem functions (29).
635 With such findings, it appears that we are closer to
636 understanding the evolutionary drivers of Darwin's
637 entangled bank and the interconnectedness of species
638 in complex communities. 639
